The production of biofuels can only be justified if their economic and environmental impacts are favourable, compared to similar energy sources, and if there are real benefits to all segments of society directly involved. One of the innovations of science and technology that should be incorporated into the production of sugarcane is the Precision Agriculture (PA), which allows the producer to understand and control more precisely the inherent spatial variability found in the fields in order to obtain higher productivity, economic return and environmental protection. In this context, this project has as main objective the evaluation of the causes of spatial and temporal variability of sugarcane productivity in order to optimize the agricultural management through AP technique. The specific objective are identify the factors, and their interactions that influence the spatial variability of yield and quality of sugarcane. The project aim to improve agronomic diagnostic models and guide the development of sensors that allow a determination “on-the-go” of soil parameters to complement the scientific knowledge needed to extend the full potential of AP as an effective tool of crop management on a commercial scale. For this, two areas cultivated with sugarcane, each with 50 ha, one area applying PA concepts, such as fertilizer application at varied rate and one area with standard management, were evaluated regarding their soil attributes, chemical and physical, and plant nutritional status. This research project, seeks to contribute to the technical/scientific knowledge about the spatial variability of sugarcane productivity through: survey of more detailed data, to assist in understanding the crop response to variations in soil and climate conditions within the cane fields. Then, contribute to the development of new management strategies for sugarcane, aiming a vertical integration of productivity and reduction of environmental and economic impacts.
SUMMARY OF RESULTS TO DATE AND PERSPECTIVES

The experiment comprised a diversity of technologies to measure soil and plant attributes within a 50 ha sugarcane area. In our data analysis workflow, the diversity of measured attributes was treated on a common ground, providing a platform to compare data acquisition technologies and to eventually select those technologies suited for large-scale PA practice. We are working to expand the sugarcane PA database, adding data from other finished and ongoing experiments. With the expanded dataset, we expect to recognize relevant patterns that are reproduced consistently across distinct experiments. For instance, data evidenced annual change in spatial distribution of sugarcane yield as well as a correlation structure relating soil pH with concentrations of organic matter and lime elements. This type of information is valuable for future PA practice. The proposed analysis workflow applied systematically to an ever-growing dataset will help consolidating the knowledge required for effective sugarcane PA.

Through an optimised grid guided by ECa, it is possible to predict the spatial distribution of soil physical and some chemical properties using Kriging with external drift (KDE). We conclude that KDE (using dynamic secondary information) presents advantages when using sparsely sampled points, providing more reliable estimates of the attributes. To improve prediction, more information could be added from other soil sensors in the trend model. These results offer a perspective for obtaining other attributes that must be estimated over large areas based on sparse soil samples. This method could assist farmers with crop management and ensure higher economic returns and a sustainable production system.
